**Aim:** To study the effects of distributor plate shape and conical angle on the pressure drop were studied in a pilot scale fluidized bed system.

**Methodology:** Five distributor plates (flat, concave with 5°, concave with 10°, convex with 5° and convex with 10°) were used in the study. The system was tested at two levels of sand particle size (a fine sand of 198 µm and coarse sand of 536 µm), various bed heights (0.5 D, 1.0 D, 1.5 D and 2.0 D cm) and various fluidization velocities (1.25, 1.50, 1.75 and 2.00 U<sub>mf</sub>). **Results:** The pressure drop was affected by the shape and the conical angle of distributor plate, sand particle size and bed height. Less than theoretical values of the pressure drop were observed with the 10° concave distributor plate at lower fluidizing gas velocities for all bed heights. A decrease in the angle of convex and an increase in the angle of concave resulted in a decreased pressure drop. Greater values of pressure drop were obtained with larger sand particles than those obtained with small sand particles at all fluidizing velocities and bed heights. For all distributor plates, increasing the bed height increased the pressure drop but decreased the ratio of pressure drop across the distributor to the pressure drop across the bed ( $\Delta_{PD}/\Delta_{PB}$ ). There was no variation in the pressure drop in the freeboard. **Conclusion:**Fluidizing gas velocities higher than 1.25 U<sub>mf</sub> should be used to for a better fluidization, improved mixing and avoiding slugging of the bed.

#### 19 20 **1. INTRODUCTION**

21

22 Cereal straws have come in recent years to be regarded as an unwanted companion of the 23 cereal crops. Their use as animal feedstuff, livestock bedding materials, erosion control agents, building materials, chemical sources, pulping material and craftwork materials have 24 25 diminished [1]. These residues can be better utilized by converting them directly to energy 26 (by combustion) or to energy carrying products (by gasification, pyrolysis and fermentation). 27 These products could be used to meet farm energy needs or be transported for use of farm 28 [2]. The organic carbon formed within the biomass during photosynthesis is released during 29 combustion of biomass (or biofuels driven from biomass), making biomass a carbon neutral 30 energy source [3, 4]. The conversion of biomass into usable energy sources represents a 31 vital method of reducing fossil fuel dependence and greenhouse gas emission. The low levels of impurities in biomass lead to lower  $SO_x$  and  $NO_x$  emission during combustion and thus reduced contribution to acid rain [5].

34

Gasification as a thermochemical conversion process can be used to convert cereal straws into syngas. One of the important features of gasification of cereal straws is that the reaction temperature can be kept as low as 600°C, thereby preventing sintering and agglomeration of the ash which occurs during the high temperature (100-1200°C) of the combustion process [6]. Fluidized bed reactors have been shown to be more suitable than moving or fixed bed reactors for the gasification of low density fuels such as crop residues because they are less prone to slagging.

42

43 The application of fluidized bed gasification technology to cereal straw is increasing rapidly 44 [7, 8]. Effective gasification of straw requires rapid mixing of the fuel material with the inert 45 sand of the bed in order to obtain a uniform distribution of the fuel particles, a better 46 chemical conversion and a uniform temperature throughout the bed [9-10,3]. However, 47 mixing problems in fluidized bed systems become very severe when fuel particles vary both 48 in size and density resulting in material segregation [7, 11-12]. One of the main causes of 49 segregation is the out of balance forces during the periodic disturbances with the passage of 50 the bubbles due to differences in density [12].

51

52 The gas distributor plate is one of the most critical features in the design of a fluidized bed 53 reactor [7]. The use of a suitable gas distributor is essential for satisfactory performance of 54 gas-solid fluidized beds [13]. Understanding of soils mixing and flow characteristics of gases 55 and solids near the grid region of a fluidized bed reactor is vitally important from the standpoint of design and scale up of gas distribution systems [14]. The presence of stagnant 56 zones near grid region can cause hot spots resulting in agglomeration and eventual reactor 57 58 failure [6]. Ghaly and MacDonald [13] developed a concave/convex type distributor plate which provided good mixing characteristics and a complete bed material turnover that 59 prevented the occurrence of stagnant zones near the grid region. 60

61

The pressure drop across the bed is another important factor to consider when designing a fluidized bed gasification system. The quality of fluidization taking place in the bed can be deduced from the bed pressure drop. Theoretically, the pressure drop across the bed should be equal to the weight of the bed particles per unit cross-sectional area of the fluidizing column as follows [15, 16]:

 $\Delta P = \frac{W}{A} \tag{1}$ 

68 69

The weight of the bed particles (W) is calculated as follows:

71 72 73

 $W = H A (\rho_p - \rho_g)(1 - \varepsilon_{mf})$ (2)

Figure 74 Equations 1 and 2 can be combined as follows:75

$$\Delta P = H (\rho_p - \rho_g)(1 - \varepsilon_{mf})$$
(3)

78 Where:

10	where.		
79	ΔP	=	Pressure drop (kPa)
80	W	=	Weight (g)
81	A	=	Cross sectional area (cm <sup>2</sup> )
82	g	=	Gravitational constant (9.8 cm/s <sup>2</sup> )
83	Н	=	Height of fixed bed (cm)
84	$ ho_{ m p}$	=	Density of the particle (g/cm <sup>3</sup> )

- 85  $\rho_g$  = Density of fluidizing gas (g/cm<sup>3</sup>)
- 86  $\epsilon_{mf}$  = Bed voidage at minimum fluidization (-)
- 87

88 However, several studies showed that the pressure drop across the fluidized bed is slightly 89 larger than the weight of the bed particles per unit cross-sectional area [17, 18]. These 90 authors indicated that both experimental and calculated pressure drops were smaller than 91 the value estimated from the gravity of the particles because the particles present do not 92 fluidize uniformly. Menon and Durian [17] reported that the pressure drop across the 93 fluidized bed reactor is normalized by the weight of the entire bed per unit area. Taghipour et 94 al. [18] reported that the overall bed pressure drop decreased significantly at the beginning 95 of fluidization and fluctuated around steady state due to bubbles being continuously split and 96 coalesce in a transient. Kawaguchi et al. [19] reported that there will be strong pressure 97 fluctuations when bubbling and slagging occurs is estimated from the gravity of the particles 98 because the particles present do not fluidize uniformly.

99

100 Pressure drop fluctuations have been observed in gas fluidized beds is a good method 101 determining fluidization quality. Large fluctuations may indicate slugging and no fluctuations 102 at all may indicate severe channeling in the bed. Moderate fluctuations indicate good 103 fluidization. Therefore, for a good gas particles distribution, distribution plates are designed 104 such that gas passing a through them experience sufficient pressure drop to prevent the 105 formation of channels in the bed. Geldart and Beayens[20] have shown that the pressure 106 drop ( $\Delta P$ ) across a distributor plate can be calculated as follows: 107

$$\Delta P_d = \frac{\rho_{g \, U^2}}{2 \, C_d^2 F^2} \tag{4}$$

108

109 Where:

110  $\Delta P_d$  = Pressure drop across distributor plate (kPa)

111  $\rho_g$  = Density of fluidizing gas (g/cm<sup>3</sup>)

112 U = Fluidizing gas velocity (cm/s)

113 C<sub>d</sub>= Discharge coefficient (-) 114 F = Fractional free area (-)

114 115

The discharge coefficient ( $C_d$ ) depends on the shape of the plate orifice (hole) fractional free area (F). Also, the thickness of the plate affects the discharge coefficient and hence the pressure drop. The thicker the distributor plate, the lower the pressure drop across the plate [21]. Clift [22] showed that for square-edged circular orifice with diameter ( $d_0$ ) much larger than the plate thickness ( $t_p$ ), $C_d$  can be taken as 0.6 for  $t_p/d_0$  greater than 0.09. Qureshi and Creasy [21] gave the following correlation between  $C_d$  and  $t_p/d_0$ :

123 
$$C_d = 0.82 \left[\frac{t_p}{d_o}\right]^{0.13}$$
(5)

124

125 Where:

126  $d_0$  = Orifice diameter (cm)

127  $t_p$  = Plate thickness (cm)

128

The pressure drop across the distributor plate can be calculated as a function of the bed pressure drop and aspect ratio using the following correlation [21]

132 
$$\frac{\Delta P_D}{\Delta P_B} = 0.01 + 0.2 \left[ 1 - \exp\left(-0.5 \frac{D}{H_{m_f}}\right) \right]$$
(6)

- 135 D = Bed diameter (cm)
- 136 $H_{mf}$  = Bed height at minimum fluidization (cm)137 $\Delta P_d$  = Pressure drop across distributor plate (kP<sub>a</sub>)
- 138  $\Delta P_{\rm b}$  = Bed pressure (kP<sub>a</sub>)
- 139

Pressure drop across the distributor plate can be used to deduce information regarding solids circulation patterns and to show whether the performance of the plate is changing with time or not. The main aim of the study was to investigate the effects of distributor plats configuration (shape and angle) on pressure drop in a bubbling fluidized bed gasification system operating at room temperature and various levels of sand particle size, bed height and fluidization velocity.

146

148

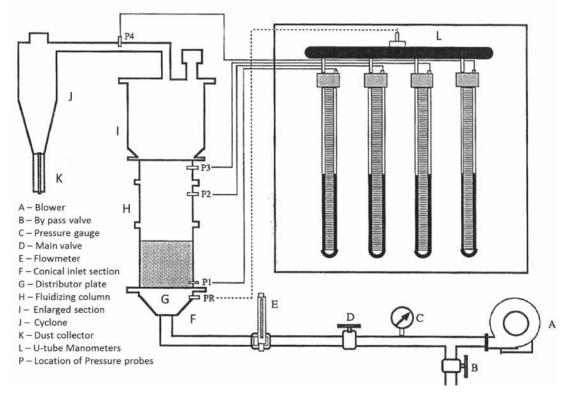

# 147 2. EXPERIMENTAL APPARATUS

The experimental apparatus used in this study is shown in Figure 1. The system consisted of: (a) a fluidized bed reactor, (b) an air supply unit, (c) a cyclone and (d) a pressure drop measurement system. With reference to Figure 1, the following are detailed descriptions of the system components.

# 153154 2.1. Fluidized Bed Reactor

155 The fluidized bed reactor consisted of: (a) a support stand, (b) a conical inlet section, (c) a

distributor plate, (d) a fluidizing column, (e) a disengagement section and (f) an outlet duct.

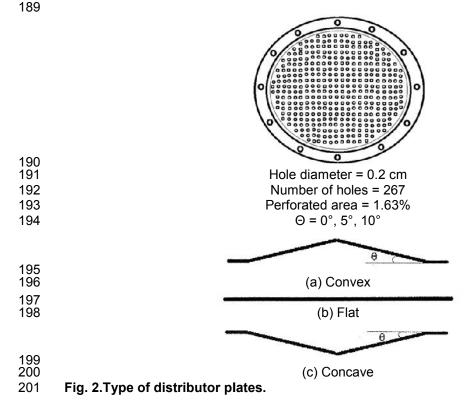

161 The support stand was constructed of 3.8 cm steel angle iron. A horizontal square structure 162 made of four 38 cm long angle iron arc welded together was supported by four 47/5 cm long 163 legs. These were arc welded to the corners of the square structure. The legs were inclined at 164 15° from vertical for stability; thereby giving a stand floor base of 52.5 cm x 52.5 cm. The 165 total height of the support stand was 46 cm. At the middle of each side of the square 166 structure, a .06 cm thick L-shaped steel extension was welded in a vertical position so that the flange of the conical inlet section of the fluidized bed reactor could lay on these 167 168 extensions. Four 0.8 cm x 3.0 cm hex head bolts were used to fix the inlet section to the 169 support stand.

170

171 The vertical section of the airline was connected to a conical (funnel shaped) inlet section 172 made of 0.32 mm thick stainless steel material. The height of the conical section was 12 cm. 173 Its sides were inclined at 45°C from vertical. The bottom and top diameters of the conical 174 section were 6/3 cm and 25.5 cm, respectively. A flange (collar) made of 0.8 cm thick 175 stainless steel was welded to the upper portion of the funnel. The inner and outer diameters of the flange were 25.5 cm and 35.5 cm, respectively. A thick rubber gasket of 0.3 mm 176 177 thickness was used between the flanges of the conical inlet section and the distributor plate 178 to provide good sealing.

179

180 The distributor plate was made of 0.8 mm thick circular steel plate of 35.5 cm diameter. A 181 circular area of 22 cm diameter was perforated. The total open area of the holes was 1.63% of the bed cross-sectional area. A total of 267 holes of 0.2 cm diameter each were drilled in 182 183 the circular plate in the form of rings starting from the center with a pitch of 1.11 cm. To prevent falling of the sand through the holes of the distributor plate, a circular screen of 100 184 mesh size was point welded to the top of the distributor plate. Five plates having exactly the 185 186 same open area and same number of vertical holes were manufactured (10° concave, 5° 187 concave, flat, 5° convex and 10° convex) and used to test the effect of distributor plate 188 configuration on the pressure drop in the fluidized bed (Figure 2).

202 The main body of the fluidized bed (fluidizing column) was made of a Plexiglas cylinder 203 having 25.5 cm inside diameter and 5 mm thickness. It was constructed in three pieces 204 having lengths of 12.75, 25.5, 38.25 cm (0.5, 1.0, 1.5 D), respectively. This provided a 205 maximum height of 76.5 cm. Two flanges made of 0.8 cm thick circular plates were glued to 206 the top and bottom of each cylinder. The height of the fluidizing column was varied by fitting 207 different sections of varying lengths. The sections were bolted to each other and rubber type 208 O-rings of 0.3 cm thickness were used between them to provide good sealing. A 5.5 cm 209 diameter port was provided near the bottom of the bed to remove the bed material when 210 required.

211

To decrease the rate of elutriation from the top of the fluidized bed, an enlarged section was used at the upper part of the bed. This part was made from 0.2 cm thick, hot rolled steel. The sides were inclined at  $30^{\circ}$  from vertical. The bottom and top diameters were 25.5 cm and 35 mc, respectively. The total height of this enlarged section, including the inclined part, was 39.5 cm. the top of this enlarged section was covered with 6 mm thick hot rolled steel, which was connected to the outlet duct.

218

The outlet duct was made of 0.16 cm thick stainless steel material. The vertical section of the duct was 10 cm in length whereas the horizontal section of the duct was 40 cm in length. The vertical section of the duct had a cross-section of 8.5 mm x 8.5 cm at the bed exit whereas the horizontal section has a cross section of 8 mm x 4 cm at the cyclone inlet.

# 224 2.2. Air Supply

225 226 The air supply system consisted of: (a) a blower equipped with a filter, (b) a pressure gauge, 227 (e) a main valve, (d) a by-pass valve, (e) and air line and (f) a flow meter. A blower (Model 228 Engenair R43 1 OA-2-220 volts and 1 3 .4 amps Benton Harbour, MI, USA) having a 229 maximum flow rate of 81.2 L/s was used. The blower was powered by a 4.8 hp, 3 phase 230 electric motor (Blador Industrial motor, 5711, Fort Smith, Arizona, USA) and ran at a speed 231 of 2850 rpm. The maximum pressure that can be obtained from the blower was 212 cm  $H_2O$ 232 (2.08 kPa). A filter having a pore size of 25 µm and a maximum flow of 7080 L/min was used 233 at the blower inlet to filter the incoming air in order to supply dust and water free air to the 234 fluidized bed reactor. The airline, through which the air was supplied to the fluidized bed, 235 was composed of horizontal and vertical steel pipe sections. The horizontal section on which 236 the flow meter and main valve were mounted was connected to a 60 cm long horizontal steel 237 pipe having an inner diameter of 6.3 cm. This was connected to a 10 cm long vertical pipe by 238 a 90<sup>°</sup> elbow having the same inner diameter. The bypass valve was located on the vertical 239 pipe. A pressure gauge (USG) having a pressure range of 0-690 kPa with a scale of 13.8 240 kPa increments was used at the exit of the blower to check the pressure level in the air 241 supply line in order to maintain atmospheric pressure in the bed. The main valve was used 242 to control the air flow rate while the by-pass valve was used to by-pass the excess air to 243 avoid over heating of the motor.

244

245 The flow rate of the fluidizing air was measured using Flow Cell Bypass Flow meter (a FLT 246 type Cole Parmar Catalog No. N03251-60, Chicago, IL). This flow meter is accurate to 2.5 247 percent of full scale and can be used up to maximum temperature and pressure of 60 °C and 248 1035kPa, respectively. Three flow meters (with different ranges 2.4-11.8, 5.6-25.5 and 11.8-249 52.1 L/s) were used depending on the required air flow rate. Each flow meter was installed in 250 a horizontal pipe having the same flow meter size rating. The length of the pipe section 251 downstream the flow meter was kept greater than three times the diameter of the pipe 252 whereas that upstream the flow meter (after the valve) was greater than eight times the 253 diameter of the pipe.

#### 255 2.3. Cyclone

256

257 A cyclone connected to the outlet duct was used to capture the fine solid particles escaping 258 from the top of the bed. The cyclone was made from a 0.2 cm thick stainless steel metal 259 sheet. It consisted of a conical and a cylindrical section. The cylindrical section had a 1 50 260 mm diameter and a 30 cm height. The conical section had a 30 cm height and its sides were 261 inclined at loo from the vertical. A gas outlet pipe of 7.5 cm diameter was extended 9 cm 262 axially into the cyclone. At the bottom of the cyclone, the fine dust particles were collected in 263 a cylindrical Plexiglas dust collector of a 6 cm diameter and a 20 cm height. 264

#### 265 2.4. Pressure Drop Measurement System.

266 The pressure drop was measured at different heights of the fluidized bed using vertically 267 mounted U-tube manometers. The first measurement point was located in the bed (5 cm 268 above the distributor plate) was used to measure the pressure drop across the distributor 269 plate. The second and third measurement points were located in the freeboard, 60 and 72 270 cm above the distributor plate, respectively. The fourth measurement point was located on 271 the outlet duct, connecting the bed exit to the cyclone. All of these pressure measurements 272 were done with respect to a reference point located at the conical inlet section (5 cm below the distributor plate). All five U-tubes were mounted on a vertical plate. Colored water was 273 274 used as the manometer liquid. Each measurement point was connected to a different U-tube 275 using flexible, tygon tubing of 10 mm diameter. The other end of the U-tube was connected 276 to the reference point through a manifold. 277

#### 278 3. EXPERIMENTAL PROCEDURE\ 279

#### 280 3.1. Experimental Design 281

282 In this study, the effects of 5 parameters on the pressure drop were investigated. The 283 experimental parameters are shown in Table 1. These were: (a) pressure drop location, with 284 4 levels, (b) type of distributor plate, with 5 levels, (c) sand mean particle size, with two 285 levels, (d) bed height, with 4 levels and (e) fluidizing velocity, with 4 levels. Three 286 measurements were taken during each experimental run.

287

#### 3.2. Determination of Particle Size 288

289 Two types of sand were used in the study: fine and course. The most common method used 290 to measure the size of irregular particles larger than 75 mm is sieving [23]. Sieving operation 291 was performed for both types of the sand used in the experiments. After sieving the mean 292 size of the particles was determined using the following equation: 202

$$d_p = \frac{1}{\sum_{i=1}^{X_i} d_{pi}} \tag{7}$$

295

296 Where: 297

d = Mean size of the particles (cm)

298  $x_i$  = Weight fraction of powder of size (-) d<sub>pi</sub> = Mean sieve size of a powder (cm)

299 300

301 The particle size distributions of the fine and coarse sands are given in Table 2 and 302 represented in Figure 3.

314

#### 315 **3.3. Determination of Pressure Drop across the Distributor Plate**

The pressure drop across the distributor plate (PD) was taken to be 10% of the pressure drop across the bed (PB). The pressure drop across the bed (PB) was determined from Equation 2. Reynolds number for the total flow approaching the plate was calculated and the corresponding value for the orifice coefficient (Cd) was selected according to the procedure

326 327

322 Fig. 3.Sand particle distribution.

described by Kunii and Levenspiel[24]. The velocity of fluid through the orifices (Uo) was
 determined as follows:

$$U_o = C_d \frac{0.5}{\rho_g} \tag{8}$$

328 Where:

 $U_{o} = \text{Gas velocity through the orifices (cm/s)}$   $U_{o} = \text{Gas velocity through the orifices (cm/s)}$   $P_{D} = \text{Pressure drop across the distributor (kPa)}$   $C_{d} = \text{Discharge coefficient (-)}$   $C_{d} = \text{Discharge coefficient (-)}$ The fraction of open area was found from the ratio U<sub>0</sub>/U<sub>s</sub>. Deciding on the orifice diameter

 $(d_o)$ , the corresponding number of orifices per unit area of distributor plate (N<sub>or</sub>) was determined as follows.

336 337

339

340

341 342

$$N_{or} = \frac{4U_s}{\pi (d_{or})^2 U_o} \tag{9}$$

338 Where:

 $N_{0r}$  = Number of orifices per unit area (-)

d<sub>0</sub> = Diameter of the orifice (cm)

U<sub>s</sub> = Superficial gas velocity (cm/s)

# 343 **3.4. Determination of the minimum fluidization velocity**344

The minimum fluidizing velocity was calculated using the following equation [25]: 346

347 
$$U_{mf} = \frac{\mu_g}{\rho_p d_p} [C_1^2 + C_2 Ar] - C_1$$
(10)

348 Where:

349  $\mu_g$  = Viscosity of the fluidizing gas (g/cm s) 350  $\rho_g$  = Density of fluidizing gas (g/cm<sup>3</sup>)

351 
$$\rho_p$$
= Density of fluidizing gas (g/cm<sup>3</sup>)

352 C<sub>1</sub> = 27.2

353  $C_2 = 0.04086$ 

354355 Archimedes number (A<sub>r</sub>) can be calculated as follows [26]

356

$$A_r = \frac{\rho_g d_p^3 (\rho_p - \rho_g)g}{\mu_g^2} \tag{11}$$

## 357 **3.5. Experimental Protocol**

358

The Selected distributor plate was fixed in place and the fluidizing column was assembled. One type of sand (fine sand) was then added to the reactor up to the required bed height. The blower was turned on and the flow rate was adjusted until the required fluidizing velocity was obtained. The pressure differences measured at various points above the distributor plate was recorded. This was then repeated 3 times with a ten minute time interval between measurements. The air flow rate was then changed and the procedure was repeat until three measurements were taken for each of the flow rates.

More sand was then added to the desired bed height and the same procedure was followed until three measurements were obtained for all bed height-flow rate combinations. The sand was changed (course sand) and the above experiments were repeated as with the other type (fine sand) of sand. Finally, the distributor plate was changed and all the above experiments were repeated with all distributor plates.

## 373 4. RESULTS AND DISCUSSION

374

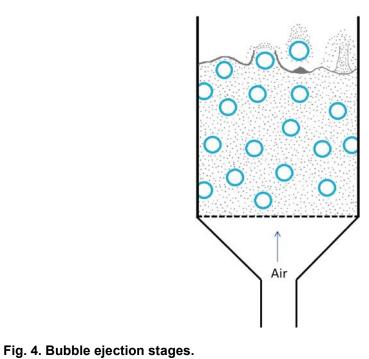

The effect of the shape and angle of distributor plate on the pressure drop in a bubbling fluidized bed reactor was investigated at various levels of sand particle size, bed height and fluidizing velocity. The pressure drop was measured at four locations in the reactor. Three pressure drop measurements were taken for each treatment combination.

379

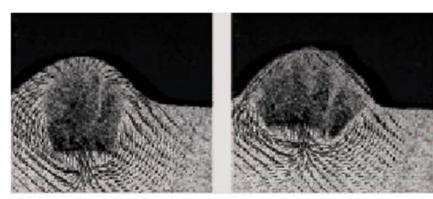

380 The analysis of the high speed films indicated that vertical transport and mixing of particles 381 were achieved by bubble motion as each bubble carried a wake of particles that was 382 ultimately deposited on the bed surface (Figure 4). It caused a drift of particles to be drawn 383 up as a spout below it as it left the bed of sand. Muller et al. [27] used particle image 384 velocimetry to capture the radial mixing that occurs during bubble burst as shown in Figure 385 5. When the bubble rises to the surface, the bubble roof breaks down and the bubble erupts. 386 The bubble wake is ejected from the surface and then falls. The surface appears settled till 387 another bubble erupts.

388

389 The shape (concave, convex or flat) and the angle of the distributor affected the vertical and 390 localized mixing as well as the upward/downward movement of sand particles (Figure 6). 391 With the concave distributor plate, there was an observed upward movement close to the 392 wall of the fluidizing column. These resulted in a completed bed material turn over in addition 393 to the localized mixing caused by the bubbles movement. The surface of the expanded 394 material took a concave shape and the degree of curvature was affected by the distributor 395 plate angle. When using the convex distributor plate the upward movement was observed at 396 the center which also resulted in a complete bed material turn over. The surface of the 397 expanded bed material took a convex shape and the degree of curvature was also affected 398 by the distributor plate angle of convex. The flat distributor plate achieved good fluidization 399 and a uniform bed material expansion. Localized mixing caused by the upward movement of 400 the bubbles was clearly evident but no bed material turnover was observed.

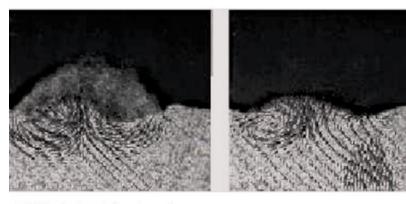

405

(a) Bubble rises to the surface

#### 411 Fig. 6. Effect of distributor plate on the mixing pattern in a bubbling fluidized bed.

412

An analysis of variance was performed on the data as shown in Table 3. The effects of five variables (the sand particles size, the bed height, the distributor plate angle, the fluidizing velocity and the location of measurement) were high significant at the 0.001 level. The analysis of variance also showed that the interactions between the various variables were highly significant at the 0.001 level.

418

419 In order to test the differences among the levels of each of the variables, Duncan's Multiple 420 Range Test was carried out on the data. The results are shown in Table 4. The 10° convex 421 and 10° concave were not significantly different from one another at the 0.5 level. Also, the 5° 422 convex, 5° concave and flat plates were not significantly different from one another at the 0.5 423 level. The highest pressure drop was observed with the 10° convex. The two particle sizes 424 were significantly different from one another at the 0.5 level and higher pressure drop was observed with the course particles. The three bed heights were significantly different from 425 426 one another at the 0.5 level. The highest pressure drop was observed with the 2D bed 427 height. The two fluidization velocities were significantly different from one another at the 0.5 428 level. The highest pressure drop was observed with the higher fluidization velocity of 1.75 429  $U_{mf}$ . The first bed location above the plate (P<sub>1</sub>) was significantly different from the other 3 430 locations (P<sub>2</sub>, P<sub>3</sub> and P<sub>4</sub>) while these three locations were not significantly different from each 431 other at the 0.05 level. The highest pressure drop was observed at the fourth location (P<sub>4</sub>). 432

# 433 **4.1. Effect of Plate Shape**

434

The results showed that there were no significant differences between pressures from measurements across the five distributor plates taken when the bed was empty (i.e. no sand in the bed). However, with the fluidized bed a decrease in the angle of concave and an increase in the angle of convex decreased the pressure drop as shown in Figure 7. It appears that the shape (angle) of distributor plate affected the average bed height (Figure 8) thereby, affecting the pressure drop.

441

Svensson*et al.* [28] investigated the influence of air distributor design on the bubble rise velocity and frequency and pressure drop of circulating fluidized bed. They reported that pressure drop across the distributor was the only significant factor affecting the fluidizing regime. Increasing the pressure drop across the distributor lead to increases in bubble size and rise time resulting in reduced residence time.

457 Sobrino et al. [29] conducted a study for measuring the distributor pressure drops in two 458 types of distributors including perforated plate and bubble cap distributor. The results 459 indicated that the pressure drop in the perforated plate distributor was due to the presence of 460 mesh which was sandwiched between the two plates. Whereas, the pressure drop across 461 bubble cap distributor is mainly due to the resistance to the flow in the entrance orifice.

462

## 463 4.2. Effect of Sand Particle Size

Greater values of pressure drop were obtained with the larger (536 mm) sand particle size (coarse sand) as compared to those obtained with smaller (198 mm) sand particle size (fine sand). On the average, pressure drops of 46.00 and 36.06 were obtained with the course and fine sand, respectively. This is due to the difference in minimum fluidization velocity of

479

477

the fine sand (4.2 cm/s) from that of the course sand (26.0 cm/s) The pressure drop across a
bubbling fluidized bed has a direct relationship with the minimum fluidization velocity of the
particles in the bed. Particles with higher minimum fluidization velocities have greater
pressure drop across the bed than particles having lower minimum fluidization velocities.

484

485 Guathier et al. [30] reported that particle size distributions have a strong influence on various 486 fluidization characteristics including fluidization velocity and pressure drop. The study was 487 carried out using four powders (narrow cut, binary mixture, Gaussian and wide cut) with 488 different particle sizes ranging from 282.5 µm to 1800 µm. The authors found that a wide 489 range of particle size has very different fluidization characteristics than powder with a narrow range of particle size. The results from the study indicated the increasing the particle 490 491 diameter (size) increased the minimum fluidization velocity (Umf.) constantly and thereby 492 increasing the total pressure drop across the bed.

493

494 Lin et al. [31] studied the effect of particle size on fluidization using four different types of powder including: a narrow powder, a binary mixture, a flat and Gaussian distribution 495 496 powder. The results indicated that particles with higher fluidization velocities tend to 497 segregate and increased the pressure drop across the bed. The results also showed that 498 binary and flat powder had higher minimum fluidization velocities ( $U_{mf}$ ) and segregated and 499 increased the pressure drop across the bed, but narrow and Gaussian distribution powder 500 had lower minimum fluidization velocities (U<sub>mf</sub>.) and were readily available for complete 501 mixing.

502 503 **4.3. Effect of Bed Height** 

An increase in the bed height increased the aspect ratio and as a result increased the pressure drop considerably. The relationship between the bed height and the aspect ratio was linear as shown in Figure 9. The value of the pressure drop varied from a low of 1.55 cm  $H_20$  to a high of 7.09 cm  $H_20$ , depending on the bed height and the distributor plate used. The pressure drop is a function of the weight of particles in the bed. Since the bed diameter is constant, an increase in bed height results in an increase in pressure drop. Similar findings were reported by Qureshi and Creasy [21].

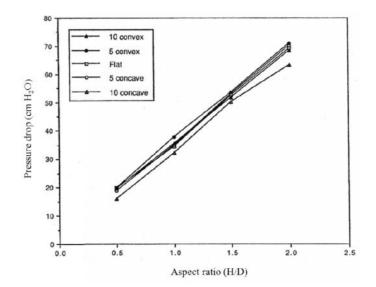

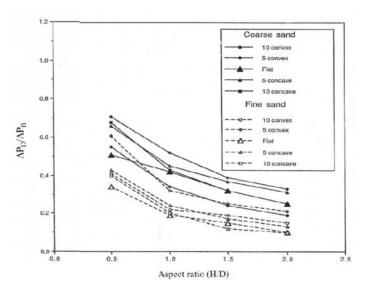

Fig. 9.Effect of aspect ratio on the pressure. 513

514

# 515

516 Fig. 10.Effect of aspect ratio on  $\Delta P_D / \Delta P_B$ .

517

518 The ratio of the pressure drop across the distributor plate to that across the bed  $(P_D/P_B)$ 519 decreased with the increase in bed height. Figure 10 shows the variation of the ratio of the experimental pressure drop to the theoretical pressure drop  $(P_E/P_T)$  with the aspect ratio at 520 521  $U/U_{mf}$ =1.75 for the two sizes of sand particles used in the experiments. The pressure drop 522 ratio decreases with the increase in bed aspect ratio for all distributor plates. Similar results were obtained with other fluidizing velocities. This agrees with the finding of Qureshi and 523 524 Creasy [21] and Geldart and Baeyens[20].

Gelperinet al. [32] studied the variation in fluidization along an angled distributor plate and 526 527 found the minimum fluidization velocity to vary from a minimum value at the site of the lowest 528 bed height (highest point of distributor plate) to a maximum at the site of the greatest bed 529 height (lowest point of the distributor plate). This variation created a gradient in the effective 530 fluidization velocity and pressure experienced in different regions of the bed.

531 Taghipour et al. [18] reported that initially the bed height increased with bubble formation 532 and then levelled off at the steady state. As a result, the bed overall pressure drop increased significantly at the beginning of fluidization and then fluctuated for about 3 s. Bi et al. [33] 533 534 reported that bed oscillations were triggered by the disturbance in the gas flow due to which 535 the bed height increased and settled after the disturbance was cut off. The authors 536 suggested that pressure variations did not result from bed height variations instead it 537 resulted due to the relaxation of layers of particles after they were displaced from their 538 original positions.

539

540 Sathiyamoorthy and Horio[34] reported that pressure drop across a distributor is 541 conventionally expressed as its ratio to bed pressure drop ( $\Delta P_D / \Delta P_B$ ) and it is in the range of 542 0.1-0.4 for a uniform operation. The authors suggested that in a deep fluidized bed, the 543 pressure drop is high and gas bypasses as large bubbles or slugs which affect heat and 544 mass transfer rates. In a shallow the bed, the pressure drop is low as it has a low transport 545 disengaging height and high a solid expansion ratio. The results from the study indicate that 546 the bed pressure ratio  $(\Delta P_D / \Delta P_B)$  decreases with increases in aspect ratio and it increases 547 with operating velocity.

548

### 549 **4.4. Effect of Fluidization Velocity**

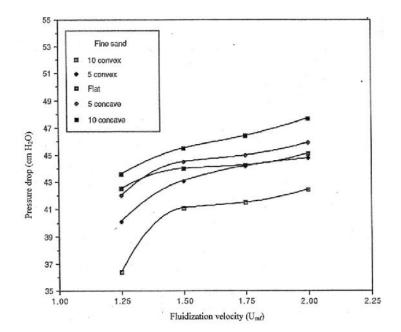

The mean value of the pressure drop was increased when the fluidization velocity was increased from 1.25 to 1.50  $U_{mf}$  as shown in Figure 11. Further increases in the pressure drop at high fluidizing velocity were very small. Generally, the pressure drop should not increase with increases in fluidizing velocity and the increase in pressure drop with increased fluidization velocityobserved in this study was more or less within experimental accuracy for ail distributor plates. This suggests that fluidizing velocities higher than 1.25  $U_{mf}$ should be used in order to obtain good fluidization.

557

558 Menon and Durian [17] stated that there are three distinct regimes of behavior observed 559 when velocity  $(U_s)$  is increased from zero. In the first regime, the values of velocity  $(U_s)$  are 560 small at constant bed height. At this point, the pressure drops ( $\Delta P$ ) varies linearly with 561 velocity (U<sub>s</sub>) and depth as per Darcy's law. The bed has similar properties of a static heap of 562 sand with a finite angle of repose at its surface. In the second regime, the velocity  $(U_s)$ 563 attains minimum fluidization velocity  $(U_{m})$  at which the pressure drops ( $\Delta P$ ) is equal to the 564 weight of the bed and the bed expands homogenously. At this point, the medium behaves like a fluid and the angle of repose becomes zero and heavier particles sink while the lighter 565 566 particles float. This is also called as uniformly fluidized state and no intensity fluctuations are 567 seen at this state. The third state is the inhomogeneous state where the velocity  $(U_s)$  is 568 above the threshold velocity leading the rising up as bubbles with a well-defined interface 569 surrounded by a granular medium having a mushroom-cap shape. In this state, the bed 570 expands with increase in velocity ( $U_s$ ) with no change in pressure ( $\Delta P$ ). In this study, the 571 pressure drop ( $\Delta P$ ) was studied across the fluidized bed at three different particle sizes (49, 572 96 and 194 µm) and velocity ranging from 0.1 to 10 cm/s. The results indicated that for all 573 particle sizes when the velocity was increased from 0.1 to 10 cm/s the pressure drop 574 increased linearly and the onset of bubbling began at a normalized pressure of 1 pgh.

575

576 Kawaguchi et al. [19] reported that when pressure drop increases the velocity of gas 577 increases, but the velocity becomes constant at a certain point after which it exhibits 578 overshoot. Inversely, when the gas velocity decreases, the pressure drop remains constant 579 and then starts to decreases when the velocity becomes too low. The minimum fluidization 580 velocity (U<sub>mf</sub>)may be determined by the velocity at which the pressure starts to decrease. In 581 this study the velocity of the gas was gradually increased to 4 m/s and then decreased 582 gradually to 0 m/s and there were high fluctuations in the pressure due to bubbling and

584 Fig. 11.Effect of fluidizing velocity on the pressure drop.

585

586 slagging and the results were averaged to obtain pressure drop values. The results indicated 587 that the minimum fluidization velocity ( $U_{mf}$ ) for the pressure was between 1.7-1.8 m/s. When the gas velocity reached 2.4 m/s the particles began to circulate in the whole region and the 588 589 bubbles were periodically formed. It was also noticed that the circulation occurs only at the 590 bottom and the particles at the top were not mixed well and the velocity at the corners was very low compared to those in the other regions. When the velocity was increased to 2.6 m/s 591 592 there was consistent bubble formations and when the bubble erupts at the surface of the 593 bed, the particles were mixed in the whole region.

#### 594

#### 595 4.5. Effect of Location of Pressure Probe

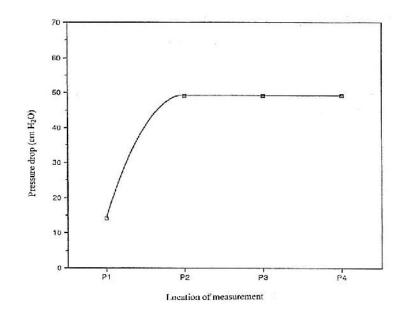

596 The pressure drop was measured across the distributor plate, at two locations in the 597 freeboards and in the duct leading to the cyclone. There were significant differences among 598 the other three locations in the freeboard and the duct as shown in Figure 12. The two points 599 in the freeboard ( $P_2$  and  $P_3$ ) gave equal pressure drop readings. This is as expected since 600 the flow conditions of the gas-solid stream were not much altered between the two locations. The finding that  $P_4$  is equal to  $P_2$  and  $P_3$  was, however, not expected. Although, the velocity 601 602 of the fluid increased at the exit due to the smaller area it was forced to pass through, the 603 pressure drop did not decrease. The reason for this is probably that the fluidizing velocities used in these experiments were not great enough to cause a great change in fluid velocity at 604 the contraction that could lead to detectable decrease in pressure drop. 605

606

507 Svoboda et al. [35] reported that location of pressure probe in the fluidized bed plays an 508 important role. Their results indicated that the maximum amplitude occurred in the middle 509 part of the fluidized bed and the amplitude tend to increase and then decrease with the 510 distance from the distributor were also detected.

611

612 Bi et al.[33] studied the effect of port spacing and probe location across the fluidized bed. 613 The authors reported that more extraneous pressure waves can be filtered out by reducing 614 the spacing between the probes but the results indicated the velocity was not greatly 615 affected by the port spacing within the test range. The flow of gas across the fluidized bed

#### 617 Fig. 12.Effect of location of measurement on pressure drop.

618

varied with axial location and different pressure peak points were obtained when the probewas moved to different locations.

621

#### 622 **6. CONCLUSIONS** 623

624 A pilot scale fluidized bed system was used to study the effect of distributor plate shape and 625 conical angle on the pressure drop. Five distributor plates (flat, concave with 5°, concave10°, 626 convex with 5° and convex with 10°) were used in the study. The system was tested at two levels of sand particle size (a fine sand of 198 µm and coarse sand of 536 µm), various bed 627 628 heights (0.5 D, 1.0 D, 1.5 D and 2.0 D cm) and various fluidization velocities (1.25, 1.50, 629 1.75 and 2.00  $U_{mf}$ ). The pressure drop was affected by the shape and the conical angle of 630 distributor plate, sand particle size and bed height. Less than theoretical values of the 631 pressure drop were observed with the 10° concave distributor plate at lower fluidizing gas velocities for all bed heights. A decrease in the angle of convex and an increase in the angle 632 633 of concave resulted in a decreased pressure drop. Greater values of pressure drop were 634 obtained with larger sand particles than those obtained with small sand particles at all 635 fluidizing velocities and bed heights. For all distributor plates, increasing the bed height 636 increased the pressure drop but decreased the ratio of pressure drop across the distributor to the pressure drop across the bed  $(\Delta P_D / \Delta P_B)$ . There was no variation in the pressure drop 637 in the freeboard. Fluidizing gas velocities higher than 1.25 U<sub>mf</sub> should be used to for a better 638 639 fluidization, improved mixing and avoiding slugging of the bed.
