

Spatial Relationship between Illiteracy and Unemployment at Governorate Level in Egypt-2006

Abstract

Most but not all studies found spatial clustering in each of illiteracy rate (IR) and unemployment rate (UR) in developing and developed countries. Question is raised whether the spatial pattern of each of IR and UR are in existence in Egypt? If so, are the spatial patterns of IR and UR spatially correlated at governorate level?

Comment [KK1]:

The objective is to investigate the spatial structure of IR and its spatial correlation with spatial structure of UR. The present study utilizes a cross-sectional census data conducted in 2006 for 27 governorates. Mapping is used as the first step to conduct visual inspection for IR and UR. Several spatial econometric techniques are available in the literature, which deal with the spatial autocorrelation in geographically referenced data. Two statistics of spatial autocorrelation, based on sharing boundary neighbours, known as global and local Moran's I , are carried out. Wartenberg's measure is used to detect bivariate spatial correlation between IR and UR based on simulation study.

Comment [KK2]:

The hypothesis of spatial clustering for IR was not confirmed by a positive global Moran's I of .03. While for UR, it was confirmed by a positive global Moran's I of .25 with $p = .008$. Bivariate spatial correlation between IR and UR was found -.19 and $p = .978$.

In conclusion, based on visual inspection of mapping global clustering was found for IR in western-northern and middle parts and for UR in eastern-northern and southern parts. Global clustering was found for UR but was not found for IR. Out of 27 governorates, two were found as local clusters in each of IR and UR. The bivariate spatial correlation between IR and UR was not found significant.

Keywords: spatial autocorrelation, unemployment, illiteracy, mapping, global and local Moran statistics, governorates of Egypt.

1. Introduction

Regions, independent of their geographic level of aggregation, are known to be interrelated partly due to their relative locations. Similar economic performance among regions can be attributed to proximity. Consequently, a proper understanding and accounting of spatial liaisons are needed in order to effectively forecast regional economic variables. Spatial statistics relates to the analysis of the spatial aspect of data sets. All data have, implicitly or explicitly, a spatial component. The reasons why spatial statistics are of import for many areas are threefold: (i) Data that are spatially close, are usually more similar than those that are further apart. Hence, there is spatial and temporal dependence for most data sets. (ii) Spatial models used to explain and make inference about data structures have important implications in many fields. (iii) The literature on spatial statistics is substantial, but there is still a lot to uncover and many questions to answer. This study showed visual picture for each of IR and UR, investigated the global and local clusters, examined the spatial relationship between UR and IR, and provides implications for policy makers.

In recent years, a growing interest has been seen in examining the existence of spatial autocorrelation for unemployment rate (UR) and its spatial relationship to several indicators such as illiteracy rate (IR), level of education, etc. across geographic areas in developing countries.

48 Historically,UR was slightly increased in Egypt from 10.6% in 2006 compared to 9.7% in 1996.
49 While IR was dramatically decreased to 29.64% in 2006 compared to 39.36% in 1996.

50
51 The spatial clustering problem of UR and IR exists in several developing and even developed
52 countries. It is very difficult to control and to find potential solutions for this problem. ~~For~~ the
53 inequality of UR and IR is affected by several factors. For example, people move continuously
54 from such governorate to other, the biasedness of the distribution of economic resources across
55 geographical locations, the job and education opportunities are much differed across geographical
56 locations, etc. We hope to achieve some improvement in reducing the inequality in UR and IR in
57 Egypt. ~~The study wants to~~ show policy makers the location of clusters problem in UR and IR.

58
59 UR and IR were studied in several countries using different statistical measures. Based on spatial
60 regression analysis, Hooghe et al. (2011) demonstrated that unemployment figures have a strong
61 and significant impact on crime rates in Belgium. According to the study in Jordan by Amerah,
62 (1993), health was affected negatively by unemployment. Amerah stated that since the mid-1980s
63 unemployment had become a serious problem in Jordan, manifesting a widening gap between the
64 demand for and supply of labour. Lack of well-paying jobs, little education and illiteracy are all
65 associated with poverty (Arab Republic of Egypt, 2007). Elhorst (2003) proposed several reasons
66 that make the study of spatially uneven distribution of unemployment worthwhile. One of these
67 reasons is the wide unemployment differentials imply inefficiency in the economy as a whole and
68 reduces growth. Jin et al. (1995) found a strong positive association in Canada between
69 unemployment and many adverse health outcomes. El-Gamal (2012) stated that illiteracy has been a
70 major issue for the government as it prevents several millions of Egyptian citizens from
71 contributing effectively to the economy of the country. The negative impact of illiteracy on
72 individuals and society makes it a key obstacle that threatens the efforts towards achieving integral
73 and comprehensive development. Osman, Zakareya, and Mahrous (2006) emphasized the
74 importance of education for the alleviation of poverty and the adversities that are particularly
75 associated with illiteracy on poverty in Egypt. Some 68 million people in Arab countries are
76 illiterate, an alarming proportion that threatens development, an Arab League culture official said
77 (New York Times, 2002). In their study in Egypt, Wahba and Zenou (2005) found that the predicted
78 probability to find a job can decrease for the illiterate and the less educated workers. Unemployment
79 and illiteracy are a major concern in Egypt. In 2006, they were 10.6% and 29.64% respectively. The
80 report conducted by United Nations Development Programme and the Institute of National
81 Planning (2003) stated that the relatively high UR among females was influenced by their higher
82 rates of illiteracy. Unemployed and/or illiterate persons have an increased risk of death. These
83 persons are facing financial problems regarding the quality of living conditions.

84
85 To understand the linkages between socioeconomic variables, investigation should focus on
86 features of the areas rather than on the compositional characteristics of residents of the area, which
87 cannot fully describe the social environment in which people live (Macintyre, Maciver & Sooman,
88 1993). So, the aim of the research is to study geographical mapping and spatial autocorrelation
89 regarding UR and its spatial relationship to IR. Spatial autocorrelation is the term used for the
90 interdependence of the lattice data over space. It is argued that lattice data are spatially
91 correlated. We used exploratory spatial data analysis (ESDA) using lattice data. The ESDA
92 quantifies the spatial pattern in order to increase the analyst's knowledge of the spatial system. As
93 well as mapping plays an important role in monitoring disadvantaged people. Maps can reveal
94 spatial patterns that is neither recognized previously nor suspected from the examination of
95 statistics table. It reveals high risk communities or problem areas (Lawson & Williams, 2001). The

100 purpose of spatial analysis is to identify pattern in geographical data and attempting to explain this
101 pattern. Findings are expected to enhance monitoring disadvantaged people and policy interventions
102 | across governorates of Egypt. Findings also enable the decision maker to re-orient resources towards
103 sectors and governorates suffering from unemployment and illiteracy.

104
105 In this research some hypotheses were tested. Are UR and IR indicators having global clustering
106 across Egypt's governorates? Are there local clusters? If so, how many clusters are there and where
107 | are they located? Can clustering in IR be associated with clustering in UR? Governorates are tightly
108 linked by migration, commuting, and inter-governorate trade. These types of spatial interaction are
109 exposed to the frictional effects of distance, possibly causing spatial dependence of governorate
110 | labour market conditions. Some of the socioeconomic indicators such as education basically offer
111 greater chance of getting a job. The parents viewed poverty as illiteracy and the inability to earn
112 better incomes (UNICEF, 2010).

113
114 | Research relevance stems from a statement that reducing UR and IR inequality is not a primary
115 objective but emergent prosperity. The importance of research objective emanates that health was
116 affected negatively by UR and IR. The report of UNICEF (2010) stated that factors that increase
117 vulnerability to HIV include a rise in mobility, the high IR especially among women, poverty, and
118 UR. It is very necessary for policy makers to know in which area the problem of UR and IR
119 inequality is existed? Also, to authors' knowledge, no studies used spatial analysis techniques and
120 geographical mapping in studying the inequality in UR and IR in Egypt.

121
122 Importance of mapping was stated by Koch (2005): why make the map if detailed statistical tables
123 carry the same results? Perhaps the most important reason for studying spatial statistics is not only
124 interested in answering the "how much" question, but the "how much is where" question
125 (Schabenberger & Gotway, 2005). In light of these: (1) the existence of spatial global clustering, (2)
126 spatial local clusters for each of UR and IR were investigated, (3) mapping was applied for each of
127 UR and IR and for their local Moran's I_i values, and (4) bivariate spatial correlation between UR
128 and IR was examined based on Wartenberg's (1985) measure. The study design was a cross-
129 sectional analysis in a census survey conducted in Egypt in 2006. Findings make a significant
130 contribution by moving beyond the investigation of a single socioeconomic resource. However,
131 findings push us to more fully consider where and why UR and IR matter.

132
133 The paper was structured as follows: Section one review the literature of UR and IR inequality
134 generally in several developing countries and particularly in Egypt. Materials and methods
135 including data details and statistical analysis are presented in second Section. Third section shows
136 the results with some details. Discussion is explained in fourth Section. Final section is closed with
137 several conclusions.

2. Materials and methods

2.1.Data

Data were collected from the book of Egypt's description by information (2009), based on census conducted in Egypt in 2006. For each of 27 governorates, UR and IR were studied. UR is an average number of unemployed individuals at the age category (15-64) years who are capable to and looking for work but unable to find a job. It is estimated as a percentage of labor force. UR varied geographically in 2006. In urban, lower, upper and frontier governorates were 12.1%, 11.0%, 9.4%, and 10.0% respectively. UR fell from round 12% of the labour force in 1998 to 10.6% in 2006. IR is defined as the percentage of persons who cannot read or write (10 years old or more, not in school). In Egypt, the IR was drastically decreased from 39.36% in 1996 to 29.64% in 2006.

2.2. Analysis

Data analysis involved six steps. In step 1, UR and IR were tested for normal distribution. They were found to follow approximately normal distribution. In step 2, visual inspection based on the quantified gradients for each of UR and IR using quartiles were conducted. Step 3 included the calculation of global Moran's I -statistic for each of UR and IR to detect the global clustering. The significance of I -statistic using permutation test was examined. Step 4 involved the calculation of local Moran's I_i for i th governorate and its p -value using Monte Carlo simulation to detect the local clusters for each of UR and IR. In step 5, using quartiles, visual inspection for the gradients of local Moran values was inspected based on choropleth mapping. In Step 6, the bivariate spatial correlation between UR and IR was examined based on Wartenberg's (1985) measure.

The UR and IR were categorized into four intervals. These intervals were used for all maps using darker shades of gray to indicate increasing values. Such approach enables qualitative evaluation of spatial pattern. In the neighbourhood researches, neighbours may be defined as governorates which border each other or within a certain distance of each other. In this research neighbouring structure was defined as governorates which share a boundary. The *second order* method (queen pattern) which included both the first-order neighbours (rook pattern) and those diagonally linked (bishop pattern) was used. A neighbourhood system of Egypt's governorates is explained in Figure 1, where ID neighbours for each governorate are shown.

Figure 1: Study area shows all governorates with its ID and ID neighbours of each governorate

To construct a choropleth map, data for enumeration governorates are typically grouped into classes and a gray tone was assigned to each class. Although maps allow visual assessment for spatial pattern, they have two important limitations: their interpretation varies from person to person, and there is the possibility that a perceived pattern is actually the result of randomness, and thus not meaningful. For these reasons, it makes sense to compute a numerical measure of spatial pattern, which can be accomplished using spatial autocorrelation.

2.2.1. Identification of global spatial clustering: The goal of a global index of spatial autocorrelation is to summarize the degree to which similar observations tend to occur near to each other in geographic space. The spatial autocorrelation using standard normal deviate (z-statistic) of Moran's I under normal assumption was tested. Moran's I is a coefficient used to measure the strength of spatial autocorrelation in regional data. The null hypothesis of no spatial autocorrelation or spatially independent versus the alternative of positive spatial autocorrelation is as follows:

H_0 : No clustering exists (no spatial autocorrelation)

H_1 : Clustering exists (positive spatial autocorrelation)

H_a : At least one cluster exists (positive spatial autocorrelation)

Formatted: Indent: Left: 1.5"
Formatted: Subscript

Moran's I is calculated as follows (Cliff and Ord, 1981):

$$I = \frac{N \sum_{i=1}^N \sum_{j=1}^N w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{S_0 \sum_{i=1}^N (x_i - \bar{x})^2} \text{ and } S_0 = \sum_{i=1}^N \sum_{j=1}^N w_{ij}, i \neq j$$

where, $N = 27$ is the number of governorates, the $w_{ij} = 1$ is a weight denoting the strength of the connection between two governorates i and j , otherwise, $w_{ij} = \text{zero}$, and the x_i and x_j represents UR or IR in the i th and j th governorate respectively.

A significant positive value of Moran's I indicates positive spatial autocorrelation, showing the overall pattern for the governorates having a high/low level of UR or IR similar to their neighbouring governorates. A significant negative value indicates negative spatial autocorrelation, showing the governorates having a high/low level of UR or IR unlike neighbouring governorates. To test the significance of global Moran's I , z -statistic that follows a standard normal distribution was applied. It is calculated as follows (Weeks, 1992):

$$z = \frac{I - E(I)}{\sqrt{\text{var}(I)}}$$

Permutation test was applied. A permutation test tells us that a certain pattern in data is or is not likely to have arisen by chance. The observations of each variable was randomly reallocated 1000 times with 1000 of spatial autocorrelations were calculated in each time to test the null hypothesis of randomness. The hypothesis under investigation suggests that there will be a tendency for a certain type of spatial pattern to appear in data, whereas the null hypothesis says that if this pattern is present, then this is a pure chance effect of observations in a random order. The analysis suggests an evidence of clustering if the result of the global test is found significant; though it does not identify the location of any particular clusters. Besides, the clustering that represents global characteristic of each of UR and IR, the existence and location of localized spatial UR and IR clusters are of interest in geographic sociology. Accordingly, local spatial statistic was advocated for identifying and assessing potential clusters.

2.2.2. Identification of local spatial clusters: A global index can suggest *clustering* but cannot identify individual *clusters* (Waller and Gotway, 2004). Anselin (1995) proposed the local Moran's I_i statistic to test the local autocorrelation. Local spatial clusters, sometimes referred to as hot spots, may be identified as those locations or sets of contiguous locations for which the local Moran's I_i is significant. However, Moran's I_i for i th governorate may be defined by Waller and Gotway (2004) as:

$$I_i = \frac{(x_i - \bar{x})}{S} \sum_{j=1}^N \left(w_{ij} / \sum_{j=1}^{N_i} w_{ij} \right) \frac{(x_j - \bar{x})}{S}, i = 1, 2, \dots, 27$$

where, analogous to the global Moran's I , x_i and x_j represent the UR or IR in the i th and j th governorate respectively, N_i = number of neighbours for the i th governorate, and S is the standard deviation. It is noteworthy to mention that the number of neighbours for the i th governorate were

241 taken into account by the amount: $\left(w_{ij} / \sum_{j=1}^{N_i} w_{ij} \right)$, where w_{ij} was measured in the same manner as
 242 in Moran's I statistic. Local Moran statistic was used to test the null hypothesis of *no clusters*.
 243

244 Cluster could be due to either aggregation of high values, aggregation of low values, or aggregation
 245 of moderate values. Thereby, high values of I_i suggesting a cluster of similar (but not necessarily
 246 large) values across several governorates, and low value of I_i suggesting an outlying UR or IR
 247 cluster in a single governorate i (being different from most or all of its neighbours). A positive
 248 local Moran value indicates local stability, such as governorate that has high/low UR or IR
 249 surrounded by governorates that has high/low UR or IR. A negative local Moran value indicates
 250 local instability, such as governorate having low UR or IR surrounded by governorates having high
 251 UR or IR or vice versa. Each governorate's I_i value was mapped to provide insight into the location
 252 of governorates with comparatively high or low local association with their neighbouring values.
 253

254 2.2.3. *Bivariate spatial association*: So far, only univariate spatial correlation is presented. It
 255 quantifies the spatial structure of one variable at a time. There is much discussion about what is an
 256 appropriate measure for bivariate spatial association. However, spatial dependence or spatial
 257 clustering causes a loss in the information that each observation carries. When N observations are
 258 made on a variable that is spatially dependent and that dependence is positive so that nearby values
 259 tend to be similar, the amount of information carried by the sample is less than the amount of
 260 information that would be carried, if the N observations are independent. Due to a certain amount
 261 of information carried by each observation is duplicated by other observations in the cluster. A
 262 general consequence of this is that the sampling variance of statistics is underestimated. As the level
 263 of spatial dependence increases, the underestimation increases. Spatial autocorrelation coefficient
 264 can be modified to estimate the bivariate spatial correlation between two variables (Wartenberg,
 265 1985):

$$I_{xy} = \frac{1}{S_0} \frac{\sum_{i=1}^N \sum_{j=1}^N w_{ij} (x_i - \bar{x})(y_j - \bar{y})}{\left[\sqrt{\sum_{i=1}^N (x_i - \bar{x})^2 / N} \right] \left[\sqrt{\sum_{j=1}^N (y_j - \bar{y})^2 / N} \right]}$$

267 where x and y represents UR and IR variables respectively. Although the mathematics is quite
 268 straightforward, very few software packages offer the option of computing I_{xy} . Thus, programming
 269 was used to find I_{xy} . To test the significance of I_{xy} , z -statistic was applied: $z = I_{xy} \sqrt{N-1}$,
 270 which follows approximately standard normal distribution.
 271

272 2.2.4. *Simulation study*: Simulated data are useful for validating the results of spatial analysis.
 273 Using Monte Carlo simulation, 9 999 random samples (27 values for each sample) were simulated.
 274 The process of simulation was conducted under standard normal distribution to calculate p -value
 275 for local Moran value. When the word simulation is used, it is referred to an analytical method
 276 meant to imitate a real-life system, especially when other analyses are too mathematically complex
 277 or too difficult to reproduce.
 278

Deleted: ing

In Monte Carlo testing, test statistic is calculated based on the data observed. Then the same statistic is calculated for a large number (say, N_{simu}) of data sets, simulated independently under the null hypothesis of interest (e.g., simulated under complete spatial randomness). The proportion of test statistic values based on simulated data exceeding the value of a test statistic observed for the actual data set provides a Monte Carlo estimate of the upper-tail p -value for one sided hypothesis test (Waller & Gotway 2004).

Specifically, suppose that $I_{i(obs)}$ denotes the test statistic for the data observed and $I_{i(1)} \geq I_{i(2)} \geq \dots \geq I_{i(N_{simu})}$ denote the test statistic values (ordered from largest to smallest) for the simulated data set. If $I_{i(1)} \geq I_{i(2)} \geq \dots \geq I_{i(l)} \geq I_{i(obs)} > I_{i(l+1)}$ (i.e., only the l largest test statistic values based on simulated data exceed $I_{i(obs)}$), the estimated p -value is given as follows:

$$p - \text{value} = \Pr(I_i \geq I_{i(obs)} | H_0 \text{ is true}) = \frac{l}{N_{simu} + 1}, i = 1, 2, \dots, N,$$

where one is added to the denominator since the estimate is based on $(N_{simu} + 1)$ values of $\{I_{i(1)}, \dots, I_{i(N_{simu})}, I_{i(obs)}\}$. While results were specific to these data, the case study helps identify general concepts for future study. In the statistical analysis, all programs performed in SPLUS8 Software.

3. Results

Descriptive statistics were calculated for each of UR and IR. The mean for UR and IR were found 10.89 and 27.55 respectively. The standard deviation for UR and IR were found 3.94 and 8.91 respectively. Skewness for UR and IR were found .84 and -.01 respectively. Kurtosis for UR and IR were found 2.37 and -1.05 respectively. The five-number summary of UR data set consisted of minimum, maximum and quartiles written in increasing order: Min=4.10, Q1=8.70, Q2=11.00, Q3=13.50 and Max=23.00. From the five-number summary, the variations of the four quarters were found 4.6, 2.3, 2.5 and 9.5 respectively, where the 4th. Quarter has the greatest variation of all. The five-number summary of IR data set was found: Min=11.63, Q1=19.47, Q2=27.44, Q3=35.08 and Max=41.29. From the five-number summary, the variations of the four quarters were found 7.84, 7.97, 7.64 and 6.21 respectively.

The values of spatial measures indicate how much and to what extent global clustering in studied variables is existed, how many local clusters are there, and where are they located. Figures 2a and 2b show visual insight for UR and its local Moran values respectively. Figures 3a and 3b show visual insight for IR and its local Moran values respectively. Darkest shade corresponds to the highest quartile. These maps display geographical variation across governorates of Egypt. Based on visual inspection of UR and IR taken from Figure 2a and Figure 3a respectively, an overall worsening pattern (higher scores) was found in the eastern-northern and southern parts and in the western-northern and middle parts respectively. The suggestion of spatial clustering of UR that follows a visual inspection of mapping was confirmed by a positive significant global Moran's I of .25 with an associated z -statistic of 2.63, $p = .008$, and permutation $p = .005$. Accordingly, the null hypothesis of no spatial autocorrelation was rejected. While, the suggestion of spatial clustering of IR that follows a visual inspection of mapping was not confirmed by a positive global Moran's I of

Deleted: T

.03 with an associated z -statistic of .59, $p = .558$, and permutation $p = .252$. This finding was not expected for IR, accordingly, the null hypothesis of no spatial autocorrelation was not rejected.

Two significant clusters in each of UR and IR were detected. Clusters of UR were located in the middle (BaniSwaif) and in the southern (Luxor) as shown in Figure 2b. Clusters of IR were located in the eastern-northern (Port Said) and in the middle (BaniSwaif) as shown in Figure 3b. Table 1 shows the name of governorate, UR, IR, local Moran's I_i for each of UR and IR and its corresponding p -value based on simulation study under standard normal distribution. The p -value in boldface was considered significant at .05 level.

The UR was not found associated with IR which is not expected. This is consistent with weak correlation (.10) between UR and IR found by Allam (2003) in Egypt. Non-spatial Pearson correlation coefficient between UR and IR was found -.23, which is not significant with $p = .249$. The bivariate spatial correlation between UR and IR was found ($I_{xy} = -.19$), which is not significant having $z = -.97$ and $p = .978$ based on simulation study under standard normal distribution. Although, the correlation values are not significant, most probably its negative direction attributed to the quality of data set and to the measurement error. It was seen that Pearson coefficient is always over estimated when it is used in finding the spatial correlation. That is why, in investigating the bivariate spatial correlation, it is recommended to use spatial measures such as Wartenberg's (1985) measure.

4. Discussion

This study, undertaken in Egypt, investigated the spatial autocorrelation of each of UR and IR, and the bivariate spatial correlation between them. Spatial global clustering and local clusters for UR and IR were examined based on global Moran's I and local Moran's I_i respectively. Bivariate spatial correlation between UR and IR was examined based on Wartenberg's measure. Such findings allow policy makers to better identify what types of resources are needed and precisely where they should be employed. The above framework revealed some noteworthy findings. After rejecting the null hypothesis for UR, concluding that there is a form of global clustering, it is of course, of interest to know the exact nature of this clustering. Are there hot-spot clusters? If so, how many hot-spots are there and where are they located? Also is this clustering associated with the clustering of IR? The population size in the governorates is not equal, i.e., the rate of UR and IR did not express the absolute size of the problem. Several governorates were not observed visually as hot spots. But after considering the information of their neighbours, the pattern of their hot spots can be obviously seen. For example, governorates 7, 8, and 26 were found in IR; and governorates 14, 15, 17, 18, and 21 were found in UR.

Maps provide powerful means to communicate data to others. Unlike information displayed in graphs, tables, and charts; maps also provide bookmarks for memories. In this way, maps were not passive mechanism for presenting information. Usually, in the spatial analysis and geographical mapping, small areas should be used such as districts, counties...etc. But, in this research governorates were used which considered somewhat larger than for example the districts because the data were not available for smaller areas. Most often the word 'neighbourhood' suggests a relatively small area surrounding individuals' homes. But researchers commonly make use of larger spatial area such as census tracts (Coulton et al., 2001). Often, the choice about neighbourhood spatial definition was made with respect to convenience and availability of contextual data rather than study purpose (Schaefer-McDaniel et al., 2010). Schaefer-McDaniel et al. (*op. cit.*) stated that, researchers might utilize census data and thus rely on census-imposed boundaries to define neighbourhoods even though these spatial areas may not be the best geographic units for the study topic.

As noted by Waller and Jacques (1995), the test for spatial pattern employs alternative hypotheses of two types; the omnibus not the null hypothesis or more specific alternatives. Tests with specific alternatives include focused tests that are sensitive to monotonically decreasing risk as distance from a putative exposure source (the focus) increases. Acceptance of either types (the omnibus or a more specific alternatives) only demonstrates that some spatial pattern exist, and does not implicate a cause (Jacques, 2004). Hence, the existence of a spatial pattern alone cannot demonstrate nor prove a causal mechanism.

Anselin (1995) stated that indication of local pattern of spatial association may be in line with a global indication, although this is not necessarily be the case. It is quite possible that the local pattern is an aberration that the global indicator would not pick up, or it may be that a few local patterns run in the opposite direction of the global spatial trend. Local values that are very different from the mean (or median) would indicate locations that contribute more than their expected share to the global statistic. These may be outliers or high leverage points and thus would invite closer scouting. However, this is found in this research. Although global clustering in IR was not found significant, two local clusters were found significant. Spatial units were arbitrary subdivisions of the study region and people could move around from one area to another. That could be affected by UR

Deleted: of

436 and IR variability in areas other than the area they live in. i.e., the variability of UR and IR in the *i*th
437 governorate was thought to be influenced and explained by the variability of UR and IR not just in
438 the *i*th governorate but also in the neighbouring governorates.

439

440 The application of statistical techniques to spatial data faces an important challenge, as expressed in
441 the first law of geography: “everything is related to everything else, but closer things are more
442 related than distant things” (Tobler, 1979). The quantitative expression of this principal is the effect
443 of *spatial dependence*. i.e., when the observed values are spatially clustered, the samples are not
444 independent. UR and IR growth in governorate *i* generates UR and IR growth in governorate *j*.

445 This mechanism of transmission causes a spatial autocorrelation of UR and IR growth. The obvious
446 | question after finding significant clusters in UR and IR is-why? Could this pattern be associated by
447 the spatial pattern of other socioeconomic indicators such as the levels of household income or by
448 the limitation of economic resources? However, further research regarding this bivariate spatial
449 association between UR and IR and other socioeconomic indicators is required. It will be of our
450 interest in the near future. This paper adds to the global body of knowledge on the utilization of
451 spatial analysis to strengthen the research-policy interface in the developing countries such as
452 Egypt.

453

454 It should be emphasized that UR and IR inequality problem cannot be overcome in the short-run; but
455 long-term efforts are needed to tackle this problem. In turn, enabling the economy to create more job
456 opportunities and establish new projects, especially in the governorates that found as hot spot
457 | clusters, means that the place of the problem is now clearly shown. Lack of investment in all levels
458 of education and other life skills result in permanent life-long inequality problem. Finally, UR and
459 IR studies should be conducted periodically in light of the changing of socioeconomic and political
460 conditions.

461

462 Details presented in this research enables development actors to identify priorities, select fields and
463 locate trends in designing national, regional, or sectorial policies. Moreover, this study provides
464 civil society organizations, researchers, and citizens with a rich knowledge base of facts and
465 analysis, offering information easy to understand and to apply. This knowledge can be used either
466 in targeted initiatives, or as a tool for monitoring and assessing policies and methods. Most
467 importantly, the research provides the information needed to both examine development strategies’
468 consistency with the actual situation, and to align priorities and develop them in accordance with
469 the Egyptian people’s development needs.

470

471 | As was not expected, spatial correlation between UR and IR was not found significant as was
472 hypothesized by some studies. Although, this work was conducted as part of a wider study, its
473 immediate implications are more for policy makers and practitioners than for researchers. Policy
474 which pays attention to area characteristics will reduce UR and IR variability. Consequently
475 improves the prosperity which in turn will improve health status. Indeed, the authors agree with the
476 statement stated by Allam (2003) that further efforts are required to meet the challenges related to
477 participation in development, particularly in the areas of illiteracy and unemployment.

478

479 To reduce the risk of unemployment in Egypt like other developing countries, efforts should focus
480 on generating growth and deregulating labor markets rather than on expanding current labor market
481 programs. Interventions that create opportunities for the poor people and reduce vulnerability
482 should have priority over traditional social assistance interventions.

5. Conclusions

Conclusions are comprehensive in at least five aspects. First, based on visual inspection of mapping, high level of UR and IR were concentrated in eastern-northern and southern parts and in western-northern and middle parts respectively. Second, several governorates were not observed visually as hot spots. But after considering the information of their neighbours, the pattern of their hot spots can be obviously seen. Third, global clustering was found in UR, but was not found in IR. Two governorates were found to be local clusters in each of UR and IR in eastern-northern, middle, and southern parts. The opposite was the case for those with low UR and IR were seen in some northern and southern parts. Fourth, from negative local Moran values, looking at local variation, some governorates represented as areas of dissimilarity in each of UR and IR. These governorates with low UR or IR were surrounded by governorates with high UR or IR, or vice versa. Fifth, spatial correlation between UR and IR was not found significant. In summary, the present study supports the hypothesis of a spatial inequality in each of UR and IR at the governorate level that probably reflects the inequality distribution in several socioeconomic indicators across the governorates of Egypt. While results were specific to these data, the case study helps to identify general concepts for future studies.
