## 16           **ABSTRACT** 17

18           Yang et al (2014) assume sealevel rise induced byglobal warming is real, and that sealevelsmayrise  
19           by 1 meter by 2100. They then go on to derive ecologicalconclusions fromthese assumptions. There is  
20           of courseno foundation for the ecological speculation if the basic assumptionsare false. Real tide  
21           gauge datashow that sealevelis risingslowly, both worldwideand the US, without any acceleration. As  
22           shown in thiscomment, the last 3 NOAA surveys of sealevel rises, compiledin 1999,2006 and 2013,  
23           indicate that the rate of sealevel rise is reducing from one survey to thenext.

26

## 27           **1. INTRODUCTION** 28

29           According to Yang et al (2014), “*The northern coasts of the Gulf of Mexico are highly vulnerable to the direct threats of climate change, such as hurricane-induced storm surge, and such risks are exacerbated by land subsidence and global sea-level rise*”. The paper then presents an application of a coastal storm surge model to study the coastal inundation process induced by tide and storm surge, and its response to the effects of land subsidence and sea-level rise. Model results suggest that hurricane-induced storm surge height and coastal inundation could be exacerbated by future global sea-level rise and subsidence.

30           It has already been documented(Parker 2013a-d; Parker, Saad Salem & Lawson, 2013; Parker, 31  
32           2014a-c) that the rates of rise of sea levels are not accelerating but only oscillating with a quasi-60  
33           years periodicity over the last few decades, while the surface air temperatures have been warming  
34           since 1910 (not since 1950 as the IPCC suggests), and also show a quasi-60 years oscillation about  
35           the longer term warming trend.

36           Several other investigations have shown that the local or global rate of rise of sea levels have  
37           been decreasing more than increasingover the last 50 years (Boretti, 2012b; Hannah & Bell, 2012;  
38           Houston & Dean, 2012; and Watson, 2011). Similarly, the changes in the rate of global sea-level are  
39           known to be influenced by a quasi-60 year oscillation (Chambers et al., 2012; Holgate, 2007; Marcos  
40           et al., 2012; Mazzarella, 2007; Scafetta, 2014; Soon & Legates, 2013). Finally, the mismatch of global  
41           sea level rise as reconstructed from tide gauges or satellite altimetry is seen as one of the biggest  
42           unsolved problems in sea level studies (Boretti, 2012a; Houston, 2013; Houston & Dean, 2012;  
43           Jevrejeva et al., 2014; Munk, 2002).

44           If we look at the tide gauge measurements, the latest PSMSL survey (PSMSL, 2014) tells us that  
45           the 170 worldwide tide gauges with more than 60 years of recording history indicate an  
46           averagerelative rate of sea level rise of 0.25mm/year. Moreover, if we focus on the 100 tide gauges

46 with more than 80 years of recording (more than 60 years of recording 20 years ago when the satellite  
47 altimetry started), the average relative rate of rise is pretty much the same, 0.24 mm/year, and this  
48 value has not changed over the last 20 years. In other words the relative sea level acceleration has  
49 been zero over the last 20 years.

50  
51

## 2. THE US AVERAGE TIDE GAUGE IS NOT ACCELERATING

52 For the United States, consistently with the worldwide average result, the long term tide gauges  
53 are only oscillating and not accelerating over the last decades (see for example Parker, 2013b-d). The  
54 latest survey published by NOAA (NOAA, 2014) shows that there is nothing actually measured that  
55 suggests sealevels have risen faster recently. While the rate of local relative change, both rises and  
56 falls, may change significantly from one location to another because of subsidence or uplift at the tide  
57 gauge, or because of phases and amplitudes of the oscillations and the time window covered, the rate  
58 of change of sea level is unequivocally small and of zero acceleration.

59 The publication by NOAA of their latest 2013 sea level survey (U.S. Linear Relative Mean Sea  
60 Level (MSL) trends and 95% Confidence Intervals (CI) Revised 10/15/2013 and downloaded on  
61 29/10/2014), when coupled to their prior surveys of 2006 and 1999, allows us to assess the non-  
62 accelerating trends along the US continental coastline, and the US territories and islands or naval  
63 bases included in the surveys.

64 To compare the results of the different surveys, we should only consider records from the same  
65 locations, with difference in the time window only originating from the additional years recorded. The  
66 comparisons of records from different starting years in the same location is misleading similarly to the  
67 comparison of the relative rate of rise in different locations. The relative rate of rise of sea levels SLR  
68 is computed as the slope of the linear fitting curve of all the recorded monthly averaged mean sea  
69 levels relative to the tide gauge location. The land movement of subsidence or uplift at the tide gauge  
70 is same order of magnitude of the relative sea level rise. For every station satisfying the comparison  
71 criteria, the conventional acceleration  $SLA(t_i)$  is computed as the difference in between the NOAA  
72 conventional rates of rise  $SLR(t_i)$  and  $SLR(t_{i-1})$  divided by the time increment  $t_i - t_{i-1}$ . The tabled NOAA  
73 surveys and the acceleration estimation are presented in the appendix.

74 This simple exercise tells us that the survey of 2006 showed a reduction of the average sea level  
75 rise compared to the values of 1999, and the latest survey of 2013 shows a further reduction of the  
76 average sea level rise compared to the 2006 survey.

77 The negative conventional acceleration was  $-0.019 \text{ mm/year}^2$  in 2006 (an average reduction of the  
78 SLR of  $-0.14 \text{ mm/year}$ ), and it is  $-0.009 \text{ mm/year}^2$  in 2013 (an average reduction of the SLR of  $-0.06$   
79  $\text{mm/year}$ ).

80 The 110 stations qualifying for the computation of the acceleration in 2013 and 2006 have an  
81 average SLR of  $1.63 \pm 0.58 \text{ mm/year}$  in 2013. In 2006 the same stations had an average SLR of  
82  $1.69 \pm 0.78 \text{ mm/year}$ .

83 The 107 stations qualifying for the computation of the acceleration in 2006 and 1999 had averaged  
84 SLR of  $1.47 \pm 0.60 \text{ mm/year}$  in 2006. The same stations had an average SLR of  $1.61 \pm 0.41 \text{ mm/year}$  in  
85 1999.

86 This evidence from recent NOAA surveys shows unequivocally that there has been no recent  
87 acceleration of sealevels for the US, just as the PSMSL surveys suggest no acceleration of  
88 sealevels worldwide, as better elaborated in the discussion.

89

## 3. DISCUSSION

90

91 To understand the global sea level rise from the relative rate of rise of sea levels from individual  
92 tide gauges is certainly very difficult. The vertical velocity of subsidence or uplift of the tide gauge is  
93 strongly variable from one site to the other. The record length is also greatly differing from one  
94 location to the other with very few tide gauges covering more than 100 years worldwide. Then,  
95 because of the multi decadal oscillations, with less than 60 years of recorded data, the relative sea  
96 level rise at the tide gauge may be largely overrated or underrated.

97 The relative rates of rise computed in the 560 tide gauges of the latest PSMSL survey (PSMSL,  
98 2014) are variable from  $+9.72 \text{ mm/year}$  to  $-17.42 \text{ mm/year}$  with an average estimation of  $+1.04$   
99  $\text{mm/year}$ . By using only the tide gauges with more than 60 years of recording, the average rate of rise  
100 in the 170 tide gauges satisfying this criteria is  $+0.25 \text{ mm/year}$ .

101 We always suggest to look at the relative acceleration of the tide gauges of enough length  
102 worldwide and for specific areas. In the latest survey of PSMSL, the 100 tide gauges satisfying the  
103 minimum requirement of 60 years recorded in the mid-1990s have an average relative rate of rise  
104

105 of+0.24 mm/year and a zero relative acceleration. Therefore, the US average tide gauge and the  
106 worldwide average tide gauge both exhibit a low relative rate of rise and no acceleration.

107 The distribution of tide gauges for the United States is relatively uniform, much better than any  
108 other location of the world except Northern Europe. More than the geographical location it is the  
109 record length that may bias considerably the surveys. The source of data are usually port authorities  
110 and independent organizations. The reliability of the relative sea level data collated by NOAA is good.  
111 The sea level data of the NOAA surveys or the PSMSL surveys have not been manipulated so far as  
112 it has been the case of other products, as for example the individual temperature records of the GISS  
113 reconstruction of the global temperature.

114 In first instance, subsidence or uplift may be considered larger time scale movements vs. the sea  
115 level rise induced by thermal expansion and ice melting. Therefore, the subsidence or uplift at the tide  
116 gauges should not have any effect on the relative acceleration of tide gauges. The relative sea level  
117 rise induced by thermal expansion and ice melting should conversely translate in a positive relative  
118 acceleration detected by the tide gauges recording with good quality over a significant time frame. If  
119 the relative acceleration is zero at the US or worldwide average tide gauge, then it means the effects  
120 of thermal expansion and ice melting are negligible.

121 Even if the IPCC claims the emissions of CO<sub>2</sub> are driving the temperatures to warm, the rainfalls to  
122 reduce, the ices to melt and the sea levels to rise, with a direct proportionality factor, nevertheless we  
123 apply the scientific method to the analyses of the measured temperatures, rainfalls, ices and sea  
124 levels to discuss what is in the data rather than what should be.

125 The simple average of the worldwide tide gauges of length above 60 years, with a 0.25 mm/year  
126 rate of rise lacking any acceleration, indicates that a tide gauges based coastal sea level rise of 1.8  
127 mm/year (reconstructed GMSL for 1880 to 2009 as from CSIRO (2014)) is a gross exaggeration, and  
128 a satellite based global absolute mean sea level rise of 3.2 mm/year (combined TOPEX/Poseidon,  
129 Jason-1 Jason-2/OSTM sea level fields as also from CSIRO (2014)) is an extreme claim.

130 The “naïve” averaging of the 170 or 100 worldwide tide gauges satisfying minimum length  
131 requirements is certainly not a measure of the global mean sea level, as the “naïve” averaging of the  
132 107-110 US tide gauges is not representing the sea level rise along the coastline of the US. However,  
133 the cherry picking of very few short tide gauge records is certainly even more questionable.

134 To make a sea level rise of 1 meter by 2100 at the worldwide average tide gauge, after 15 years of  
135 this century there are still 996.25 millimeters missed. Every model to be trusted need validation, and  
136 theories failing to reproduce the experimental evidence are not science but philosophy. Since the  
137 time the anthropogenic sea level rise theory has been proposed there has been nothing really  
138 measured that has confirmed that this theory is correct. As the sea levels should follow the carbon  
139 dioxide emission not by magic but through the temperatures (thermal expansion of ocean waters and  
140 mass addition from melting of glaciers and ice caps), there is no opportunity that the sea levels could  
141 suddenly rise the 996.25 millimeters left for this century instantaneously when they are growing 0.25  
142 mm/year with zero acceleration over the last few decades.

143 The definition of acceleration is conventional, as conventional is the usual definition of velocity  
144 (rate of rise). As the sea level oscillates with many periodicities, it is customary to define the rate of  
145 rise (velocity) as the slope of the linear fitting of the monthly average mean sea level observations. It  
146 is then logic to define a conventional acceleration based on the tabled data as the time rate of change  
147 of this velocity from one survey to another. This parameter is positive if the rate of rise increases from  
148 one survey to the other, or negative otherwise. A parabolic fitting of the monthly average mean sea  
149 level observations returns a different acceleration parameter, the average acceleration over the full  
150 length of the record that is less relevant to the present debate and cannot be computed from the  
151 tabled data.

152 The large table comparing the US Linear Relative Mean Sea Level at various locations in 1999,  
153 2006 and 2013 showing that on average sea level rate in the US has been of the order of 1.5  
154 mm/year with a nearly vanishing acceleration negative rather than positive is surely useful in the US  
155 sea level debate.

#### 157 4. CONCLUSIONS

158 Any acceleration in sea level rate rise is very likely close to zero in the US, as everywhere else in  
159 the world. With relative sea level rises of about 1.5 mm/year without any acceleration, a sea level rise  
160 of 1 meter in the US would require 666 years. This slow rate of rise, based on observations, does not  
161 support the alarmist exercise of Yang et al (2014) based on modelling.
